

On the Instability of Fractional Reserve Banking*

HEON LEE[†]

University of Missouri

October 13, 2023

Abstract

This paper develops a dynamic monetary model to study the (in)stability of the fractional reserve banking system. The model shows that the fractional reserve banking system can endanger stability in that equilibrium is more prone to exhibit endogenous cyclic, chaotic, and stochastic dynamics under lower reserve requirements, although it can increase consumption in the steady-state. Introducing endogenous unsecured credit to the baseline model does not change the main results. This paper also provides empirical evidence that is consistent with the prediction of the model. The calibrated exercise suggests that this channel could be another source of economic fluctuations.

*This paper is a revised version of Chapter 2 of my PhD dissertation at the University of Missouri. I am deeply indebted to my advisor, Chao Gu, for her guidance at all stages of this research project. I am grateful to my committee members, Joseph Haslag, Aaron Hedlund, and Xuemin (Sterling) Yan for helpful comments. I also thank Costas Azariadis, Guido Menzio, Christian Wipf and seminar participants at the 2020 MVEA Conference, 2021 EGSC, and 2021 MEA Annual Meeting for useful feedback and discussion. All remaining errors are mine.

Motivated partly by a desire to avoid such [excessive] price-level fluctuations and possible Wicksellian price-level indeterminacy, quantity theorists have advocated legal restrictions on private intermediation. ... Thus, for example, Friedman (1959, p. 21) ... has advocated 100 percent reserves against bank liabilities called demand deposit. **Sargent and Wallace (1982)**

1 Introduction

There have been claims that fractional reserve banking is an important cause of boom-bust cycles, based on the notion that banks create excess credit under fractional reserve banking. (e.g., [Fisher, 1935](#); [Von Mises, 1953](#); [Minsky, 1957](#); [Minsky, 1970](#)). For instance, [Fisher \(1935\)](#) views fractional reserve banking as one of several important factors in explaining economic fluctuations. Others believe that this is a primary cause of boom-bust cycles. According to [Von Mises \(1953\)](#), the overexpansion of bank credit as a result of fractional reserve banking is the root cause of business cycles. [Minsky \(1970\)](#) claims that economic booms and structural characteristics of the financial system, such as fractional reserve banking, can result in an economic collapse even when fundamentals remain unchanged.

This idea leads to policy debates on fractional reserve banking. Earlier examples include Peel's Banking Act of 1844 and the Chicago plan of banking reform with a 100% reserve requirement proposed by Irving Fisher, Paul Douglas, and others in 1939. Later, [Friedman \(1959\)](#) supported this banking reform, whereas [Becker \(1956\)](#) took the opposite position of supporting free banking with 0% reserve requirement.¹ Recently in 2018, Switzerland had a referendum of 100% reserve banking, which was rejected by 75.72% of the voters. The referendum aimed at making money safe from crisis by constructing full-reserve banking.² Whereas the debate on whether a fractional reserve banking system is inherently unstable has been an important policy discussion since a long time ago, the debate has never stopped.

This paper examines the instability of fractional banking by answering the following

¹[Sargent \(2011\)](#) provides a novel review of the historical debates between narrow banking and free banking as tensions between stability versus efficiency.

²The official title of the referendum was *the Swiss federal popular initiative "for crisis-safe money: money creation by the National Bank only! (Sovereign Money Initiative)"* and also titled as *"debt-free money."*

questions: (i) Can fractional reserve banking be inherently volatile even if we shut down the stochastic component of the economy? (ii) If so, under what condition can fractional reserve banking generate endogenous cycles without the presence of exogenous shocks and changes in fundamentals? To assess the claim that fractional reserve banking causes business cycles, this paper constructs a model of money and banking that captures the role of fractional reserve banking.

In the model, each agent faces an idiosyncratic liquidity shock. Banks accept deposits and extend loans to provide risk-sharing among the depositors whereas the bank's lending is constrained by the reserve requirement. The real balance of money is determined by two factors: storage value and liquidity premium. The storage value is increasing in the future value of money. However, the liquidity premium, the marginal value of its liquidity function, is decreasing if the money becomes more abundant. When the liquidity premium dominates the storage value, the economy can exhibit endogenous fluctuations. Fractional reserve banking amplifies the liquidity premium because it allows the bank to create inside money through lending. Due to this amplified liquidity premium, the fractional reserve banking system is more prone to endogenous cycles.

In the baseline model, lowering the reserve requirement increases welfare in the steady state. However, lowering the reserve requirements can induce two-period cycles as well as three-period cycles, which implies the existence of periodic cycles of all order and chaotic dynamics. This also implies it can induce sunspot cycles. This result holds in the extended model with unsecured credit. The model also can deliver a self-fulfilling bubble burst. It is worth noting that the full reserve requirement does not necessarily exclude the possibility of endogenous cycles. However, the economy will be more susceptible to cycles with lower reserve requirement.³

This paper departs from previous works in two ways. First, in contrast to the previous works on banking instability, which mostly focus on bank runs following the seminal model by [Diamond and Dybvig \(1983\)](#), this paper focuses on the volatility of real balances of inside money. It is another important focal point of banking instability because recurring boom-bust cycles associated with banking are probably be more prevalent than bank runs. Second, the approach here differs from a traditional approach to economic fluctuations with financial frictions. To understand economic fluctuations, there are two major points of view. The first one is that economic fluctuations are

³[Gu, Monnet, Nosal and Wright \(2019a\)](#) show that introducing banks to the economy could induce instability in various settings which is in line with this result.

driven by exogenous shocks disturbing the dynamic system, and the effects of exogenous shocks shrink over time as the system goes back to its balanced path or steady-state. The second one is that they instead reflect an endogenous mechanism that produces boom-bust cycles. While there has been a lot of work on the role of financial friction in the business cycles including [Kiyotaki and Moore \(1997\)](#), [Bernanke, Gertler and Gilchrist \(1999\)](#), and [Gertler and Karadi \(2011\)](#), most of them focused on the first approach, in which all economic fluctuations are caused by exogenous shocks and the financial sectors only serve as an amplifier. This paper, however, takes the second approach and focuses on whether the endogenous cycles arise in the absence of the stochastic components of the economy.

To evaluate the main prediction from the theory that fractional reserve banking induces excess volatility, I test the relationship between the required reserves ratio and the volatility in real balance using cointegrating regression. A significant negative relationship between the two variables are found, and the results are robust to different measures of inflation and different frequency of time series. Both theoretical and empirical evidence indicate a link between the reserve requirement and the (in)stability.

Related Literature This paper builds on [Berentsen, Camera and Waller \(2007\)](#), who introduce financial intermediaries with enforcement technology to [Lagos and Wright \(2005\)](#) framework. The approach to introduce unsecured credit to the monetary economy is related to [Lotz and Zhang \(2016\)](#) and [Gu, Mattesini and Wright \(2016\)](#) which are based on the earlier work by [Kehoe and Levine \(1993\)](#).

This paper is related to the large literature on fractional reserve banking. [Freeman and Huffman \(1991\)](#) and [Freeman and Kydland \(2000\)](#) develop general equilibrium models that explicitly capture the role of fractional reserve banking. Using those models, they explain the observed relationships between key macroeconomic variables over business cycles. [Chari and Phelan \(2014\)](#) study the condition under which fractional reserve banking can be socially useful by preventing bank runs in the cash-in-advance framework. For recent work, [Wipf \(2020\)](#) studies the welfare implications of fractional reserve banking in a New Monetarist economy with imperfect competition and identifies the conditions under which fractional reserve banking can be welfare-improving compared to narrow banking. [Andolfatto, Berentsen and Martin \(2020\)](#) integrate [Diamond \(1997\)](#) into [Lagos and Wright \(2005\)](#) to provide a model in which fractional reserve banking emerges endogenously and a central bank can prevent bank panic as a

lender of last resort. Whereas many previous work on instability focuses on bank runs, this paper studies a different type of instability in the sense that fractional reserve banking induces endogenous monetary cycles.

This paper is also related to the large literature on endogenous fluctuations, chaotic dynamics, and indeterminacy that have been surveyed by [Brock \(1988\)](#), [Baumol and Benhabib \(1989\)](#), [Boldrin and Woodford \(1990\)](#), [Scheinkman and Woodford \(1994\)](#) and [Benhabib and Farmer \(1999\)](#). For a model of bilateral trade, [Gu, Mattesini, Monnet and Wright \(2013\)](#) show that credit markets can be susceptible to endogenous fluctuations due to limited commitment. Using a continuous-time New Monetarist economy, [Rocheteau and Wang \(2023\)](#) show that asset liquidity can be a source of price volatility when assets have a non-positive intrinsic value. [Altermatt, Iwasaki and Wright \(2023\)](#) study economies with multiple liquid assets and show that liquidity considerations could imply endogenous fluctuations as self-fulfilling prophecies. [Gu et al. \(2019a\)](#) show that introducing financial intermediaries to an economy can engender instability in four distinct setups that capture various functions of banking. The model in this paper is closely related to [Gu et al. \(2019a\)](#), whereas the model here is extended to incorporate fractional reserve banking.

The rest of the paper is organized as follows. Section 2 constructs the baseline search-theoretic monetary model. Section 3 provides main results. Section 4 introduces unsecured credit. Section 5 discusses the empirical evaluation of the model. Section 6 calibrates the model to quantify the theory. Section 7 concludes.

2 Model

The model is based on [Lagos and Wright \(2005\)](#) with a financial intermediary as in [Berentsen et al. \(2007\)](#). Time is discrete and infinite. In each period, three markets convene sequentially. First, a centralized financial market (FM), followed by a decentralized goods market (DM), and finally a centralized goods market (CM). The FM and CM are frictionless. The DM is subject to search frictions, anonymity, and limited commitment. Therefore, a medium of exchange is needed to execute trades.

There is a continuum of agents who produce and consume perishable goods. At the beginning of the FM, a preference shock is realized: With probability σ , an agent will be a buyer in the following DM and with probability $1 - \sigma$, she will be a seller. The buyers and the sellers randomly meet and trade bilaterally in the DM. Agents discount

their utility each period by β . Within-period utility is represented by

$$\mathcal{U} = U(X) - H + u(q) - c(q),$$

where X is the CM consumption, H is the CM disutility from production, and q is the DM consumption. As standard $U', u', c' > 0$, $U'', u'' < 0$, $c'' \geq 0$, and $u(0) = c(0) = 0$. The CM consumption good X is produced one-for-one with H , implying the real wage is 1. The efficient consumption in CM and DM is X^* and q^* that solve $U'(X^*) = 1$ and $u'(q^*) = c'(q^*)$, respectively.

There is a representative bank who accepts deposits and lends loans in the FM. In the FM, the agent can borrow money from the bank for a promise to repay money in the subsequent CM at nominal lending rate i_l . The agent can also deposit money to the bank and receive money in the subsequent CM at nominal deposit rate i_d . The banking market is perfectly competitive. The bank can enforce the repayment of loans at no cost. Last, there is a central bank that controls the money supply M_t . Let γ be the growth rate of the money stock. Changes in money supply are accomplished by lump-sum transfer if $\gamma > 0$ and by lump-sum tax if $\gamma < 0$.

2.1 Agent's Problem

Let W_t , G_t , and V_t denote the agent's value function in the CM, FM, and DM, respectively, in period t . There are two payment instruments for the DM transaction: fiat money (outside money) and loans from the bank (inside money). I will allow the agents to use unsecured credit as a means of payment in the next section. An agent entering the CM with nominal balance m_t , deposit d_t , and loan ℓ_t , solves the following problem:

$$\begin{aligned} W_t(m_t, d_t, \ell_t) &= \max_{X_t, H_t, \hat{m}_{t+1}} U(X_t) - H_t + \beta G_{t+1}(\hat{m}_{t+1}) \\ \text{s.t. } \phi_t \hat{m}_{t+1} + X_t &= H_t + T_t + \phi_t m_t + (1 + i_{d,t}) \phi_t d_t - (1 + i_{l,t}) \phi_t \ell_t, \end{aligned} \tag{1}$$

where T_t is the lump-sum transfer (or tax if it is negative), $i_{d,t}$ is the deposit interest rate, $i_{l,t}$ is the loan interest rate, ϕ_t is the price of money in terms of the CM goods, and \hat{m}_{t+1} is the money balance carried to the FM where banks take deposits and makes

loans. The first-order conditions (FOCs) result in $X_t = X^*$ and

$$\phi_t = \beta G'_{t+1}(\hat{m}_{t+1}), \quad (2)$$

where $G'_{t+1}(\hat{m}_{t+1})$ is the marginal value of an additional unit of money taken into the FM of period $t + 1$. The envelope conditions are

$$\frac{\partial W_t}{\partial m_t} = \phi_t, \quad \frac{\partial W_t}{\partial d_t} = \phi_t(1 + i_{d,t}), \quad \frac{\partial W_t}{\partial \ell_t} = -\phi_t(1 + i_{l,t}),$$

implying W_t is linear in m_t , d_t , and ℓ_t .

The value function of an agent at the beginning of FM is

$$G_t(m) = \sigma G_{b,t}(m) + (1 - \sigma) G_{s,t}(m), \quad (3)$$

where $G_{j \in \{b,s\},t}$ is the value function of type j agent in the FM. Agents choose their deposit balance d_j and loan ℓ_j based on the realization of their types in the following DM. The value function $G_{j,t}$ can be written as

$$G_{j,t}(m) = \max_{d_{j,t}, \ell_{j,t}} V_{j,t}(m - d_{j,t} + \ell_{j,t}, d_{j,t}, \ell_{j,t}) \quad \text{s.t.} \quad d_{j,t} \leq m, \quad (4)$$

where $V_{j,t}$ is the value function of type j agent in the DM. The FOCs are

$$\frac{\partial V_{j,t}}{\partial \ell_{j,t}} \leq 0 \quad (5)$$

$$\frac{\partial V_{j,t}}{\partial d_{j,t}} - \lambda_d \leq 0 \quad (6)$$

where λ_d is the Lagrange multiplier for $d_{j,t} \leq m$.

The terms of trade in the DM are determined by an abstract mechanism that is studied in [Gu and Wright \(2016\)](#). The buyer must pay $p = v(q)$ to the seller to get q where $v(q)$ is some payment function satisfying $v'(q) > 0$ and $v(0) = 0$. As shown in [Gu and Wright \(2016\)](#), if the trading protocol satisfies four common axioms, then the terms of trade can be written in the following form.

$$p = \begin{cases} z & \text{if } z < p^* \\ p^* & \text{if } z \geq p^* \end{cases} \quad q = \begin{cases} v^{-1}(z) & \text{if } z < p^* \\ q^* & \text{if } z \geq p^* \end{cases}, \quad (7)$$

where p^* is the payment required to get efficient consumption q^* , and z is the total liquidity, $\phi(m - d + \ell)$, held by the buyer. Many standard mechanisms, such as Kalai and generalized Nash bargaining, are consistent with this specification.

With probability α , a buyer meets a seller in the DM while a seller meets a buyer with probability α_s . Since the CM value function is linear, the DM value function for the buyer can be written as

$$V_{b,t}(m_t - d_{b,t} + \ell_{b,t}, d_{b,t}, \ell_{b,t}) = \alpha[u(q_t) - p_t] + W(m_t - d_{b,t} + \ell_{b,t}, d_{b,t}, \ell_{b,t}), \quad (8)$$

where $p_t \leq \phi_t(m_t - d_{b,t} + \ell_{b,t})$. Assuming interior solution, differentiating $V_{b,t}$ yields

$$\frac{\partial V_{b,t}}{\partial m} = \phi_t[\alpha\lambda(q_t) + 1], \quad \frac{\partial V_{b,t}}{\partial d} = \phi_t[-\alpha\lambda(q_t) + i_{d,t}], \quad \frac{\partial V_{b,t}}{\partial \ell} = \phi_t[\alpha\lambda(q_t) - i_{l,t}],$$

where $\lambda(q) = u'(q)/v'(q) - 1$ if $p^* > z$ and $\lambda(q) = 0$ if $z \geq p^*$. Combining the buyer's FOCs in the FM and the derivatives of V_b yields

$$\phi i_{d,t} - \phi\alpha\lambda(q_t) - \lambda_d \leq 0, \text{ " = "0 iff } d_{b,t} > 0 \quad (9)$$

$$-\phi i_{l,t} + \phi\alpha\lambda(q) \leq 0, \text{ " = "0 iff } \ell_{b,t} > 0. \quad (10)$$

A seller's DM value function is

$$V_{s,t}(m_t - d_{s,t} + \ell_{s,t}, d_{s,t}, \ell_{s,t}) = \alpha_s[p_t - c(q_t)] + W_t(m_t - d_{s,t} + \ell_{s,t}, d_{s,t}, \ell_{s,t}). \quad (11)$$

Differentiating $V_{s,t}$ yields

$$\frac{\partial V_{s,t}}{\partial m_t} = \phi_t, \quad \frac{\partial V_{s,t}}{\partial d_t} = \phi_t i_{d,t}, \quad \frac{\partial V_{s,t}}{\partial \ell_t} = -\phi_t i_{l,t}.$$

Similar to the buyer's case, combining the seller's FOCs in the FM and the first-order derivatives of $V_{s,t}$ yields

$$\phi_t i_{d,t} - \lambda_d \leq 0, \text{ " = "0 iff } d_{s,t} > 0 \quad (12)$$

$$-\phi_t i_{l,t} \leq 0, \text{ " = "0 iff } \ell_{s,t} > 0. \quad (13)$$

One can show that buyers do not deposit and sellers always deposit whereas buyers always borrow loans but sellers do not. This is because the buyer needs liquidity to trade for q in the DM but the seller does not. Formally, for $m > 0$, we have

$\partial V_{b,t}/\partial d_{b,t} < \partial V_{s,t}/\partial d_{s,t} = 0$ and $\partial V_{s,t}/\partial \ell_{s,t} < \partial V_{b,t}/\partial \ell_{b,t} = 0$ because

$$0 = \overbrace{i_{d,t} - \lambda_d/\phi_t}^{\partial V_{s,t}/\partial d_{s,t}} > \overbrace{i_{d,t} - \lambda_d/\phi_t - \alpha\lambda(q_t)}^{\partial V_{b,t}/\partial d_{b,t}} \quad (14)$$

$$0 = \underbrace{-\phi_t i_{l,t} + \phi_t \alpha \lambda(q_t)}_{\partial V_{b,t}/\partial \ell_{b,t}} > \underbrace{-\phi_t i_{l,t}}_{\partial V_{s,t}/\partial \ell_{s,t}} \quad (15)$$

implying $i_{l,t} = \alpha\lambda(q_t)$, $d_{s,t} = m$, $d_{b,t} = 0$, $\ell_{s,t} = 0$, and $\ell_b > 0$ as long as $\lambda(q_t) > 0$.

Using the above results, we can rewrite the value functions in the FM as follows:

$$G_{b,t}(m_t) = \alpha[u(q_t) - p_t] + W(m_t + \ell_{b,t}, 0, \ell_{b,t}) \quad (16)$$

$$G_{s,t}(m_t) = \alpha_s[p_t - c(q_t)] + W(m_t - d_{s,t}, d_{s,t}, 0) \quad (17)$$

where $q_t = v^{-1}(p_t)$ and $p_t = \min\{p^*, \phi(m_t + \ell_{b,t})\}$. Take derivative of $G_{j,t}(m_t)$ with respect to m_t to get

$$G'_{b,t}(m_t) = \phi_t + \phi_t \alpha \lambda(q_t) \quad (18)$$

$$G'_{s,t}(m_t) = \phi_t + \phi_t i_{d,t}. \quad (19)$$

Since $G'_t(m_t) = \sigma G'_{b,t}(m_t) + (1 - \sigma)G'_{s,t}(m_t)$, we have the following:

$$G'_t(m_t) = \phi_t \sigma [1 + \alpha \lambda(q_t)] + \phi_t (1 - \sigma) (1 + i_{d,t}). \quad (20)$$

Combine (2) and (20) to get the Euler equation

$$\phi_t = \begin{cases} \phi_{t+1} \beta [\sigma \{1 + \alpha \lambda(q_{t+1})\} + (1 - \sigma)(1 + i_{d,t+1})] & \text{if } z_{t+1} < p^* \\ \phi_{t+1} \beta & \text{if } z_{t+1} \geq p^*, \end{cases} \quad (21)$$

where $q_{t+1} = v^{-1}(z_{t+1})$ and $z_{t+1} = \phi_{t+1}(m_{t+1} + \ell_{b,t+1})$

2.2 Bank's Problem

A representative bank accepts deposits d and makes loans ℓ . The depositors are paid at the nominal interest rate i_d by the bank, and the borrowers need to repay their borrowing with a nominal interest rate i_l . The central bank sets reserve requirement

χ . The representative bank solves the following profit maximization problem.

$$\max_{d, \ell} (i_l \ell - i_d d) \quad s.t. \quad \chi \ell \leq d \quad (22)$$

The FOCs for the bank's problem are

$$0 = i_l - \lambda_L \quad (23)$$

$$0 = -i_d + \lambda_L / \chi, \quad (24)$$

where λ_L is the Lagrange multiplier with respect to the bank's lending constraint. For $\lambda_L > 0$, we have

$$i_l = \chi i_d \quad (25)$$

while $\lambda_L = 0$ implies $i_d = i_l = 0$. Given the bank's problem and the agent's problem, we can define an equilibrium as follows:

Definition 1. *Given (γ, χ) , an equilibrium consists of sequences of prices $\{\phi_t, i_{l,t}, i_{d,t}\}_{t=0}^{\infty}$, real balances $\{m_t, \ell_{b,t}, \ell_{s,t}, d_{b,t}, d_{s,t}\}_{t=0}^{\infty}$, and allocations $\{q_t, X_t, \ell_t\}_{t=0}^{\infty}$ satisfying the following:*

- *Agents solve CM, FM and DM problems: (1) and (4)*
- *The terms of trade in the DM satisfy (7), (8) and (11)*
- *A representative bank solves its profit maximization problem: (22)*
- *Markets clear in every period:*
 1. *Deposit Market: $\sigma d_{b,t} + (1 - \sigma) d_{s,t} = d_t$*
 2. *Loan Market: $\sigma \ell_{b,t} + (1 - \sigma) \ell_{s,t} = \ell_t$*
 3. *Money Market: $m_t = M_t$*
- *Transversality condition: $\lim_{t \rightarrow \infty} \beta^t \phi_t m^t = 0$*

The next step is to characterize the equilibrium. With binding bank's lending constraint, the equilibrium lending satisfies $\ell_t = (1 - \sigma)m_t / \chi$ and $\ell_{b,t} = (1 - \sigma)m_t / (\sigma\chi)$. Combine equations (10), (21) and (25), and use equilibrium condition $m_{t+1} = M_{t+1}$ to get

$$\phi_t = \begin{cases} \phi_{t+1} \beta \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha \lambda \circ v^{-1}(z_{t+1}) + 1 \right] & \text{if } z_{t+1} < p^* \\ \phi_{t+1} \beta & \text{if } z_{t+1} \geq p^*, \end{cases} \quad (26)$$

Figure 1: Monetary Equilibrium

where $z_{t+1} = \phi_{t+1}M_{t+1}(1 - \sigma + \sigma\chi)/\sigma\chi$. Then multiplying both sides of (26) by $M_t(1 - \sigma + \sigma\chi)/\sigma\chi$ allows us to reduce the equilibrium condition to one difference equation of real balances z :

$$z_t = f(z_{t+1}) \equiv \frac{z_{t+1}}{1+i} \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_{t+1}) + 1 \right], \quad (27)$$

where $(1+i) \equiv \gamma/\beta$ and $L(z) \equiv \lambda \circ v^{-1}(z)$ is the liquidity premium.⁴

3 Results

This section establishes key results. Before starting a discussion on dynamics, consider stationary equilibria which are defined as fixed points that satisfy $z = f(z)$. There always exists a non-monetary equilibrium with $z = 0$. A unique solution of monetary stationary equilibrium $z_s > 0$ exists and solves

$$\chi i = (1 - \sigma + \sigma\chi) \alpha L(z_s) \quad (28)$$

when $i < \bar{i}$ where $\bar{i} = \alpha(1 - \sigma + \sigma\chi)L(0)/\chi$. Nash and Kalai bargaining provide simple examples for \bar{i} . Under the Inada condition $u'(0) = \infty$, with Kalai, $\bar{i} = \theta\alpha(1 - \sigma + \sigma\chi)/\chi(1 - \theta)$; whereas with Nash bargaining, $\bar{i} = \infty$.

⁴In the stationary equilibrium, $i = \gamma/\beta - 1$ is the nominal interest rate.

Since $L'(z) < 0$ (see [Gu and Wright, 2016](#)), the following result holds:

Proposition 1. *In the stationary equilibrium, lowering i or lowering χ increases q .*

Proof. See Appendix A. ■

Figure 1a shows examples. because it allows to create more liquidity in the economy.

The dynamics of monetary equilibrium are characterized by $f(z_{t+1})$ from equation (27). The first term, $z_{t+1}/(1+i)$ on the right-hand side, reflects the store of value, which is monotonically increasing in z_{t+1} . The second term $(1-\sigma+\sigma\chi)\alpha L(z_{t+1})/\chi+1$, reflecting the liquidity premium, is decreasing in z_{t+1} . Because $f'(z_{t+1})$ depends on both terms, $f(z_{t+1})$ is nonmonotone in general. Figure 1b provides an example. When $z < p^*$, the liquidity is scarce. When $z \geq p^*$, the buyer has enough liquidity to pay for q^* . In this case, the liquidity is abundant. Then $z_t \geq p^*$ implies and $q_t = q^*$, in which case we say liquidity is abundant because it is sufficient to buy q^* . This example shows if the reserve requirement is small, it is more likely to have the backward bending feature because the weight on the nonlinear part on the right-hand side is bigger. More backward bending features can induce an endogenous cycle. Therefore, lowering the reserve requirement amplifies the liquidity premium because it allows the bank to create more liquidity through lending. This amplification of liquidity generates endogenous cycles.

The standard treatment for showing the existence of an endogenous cycle is $f'(z_s) < -1$ (see [Azariadis, 1993](#)). In this case, the economy can exhibit a two-period cycle with $z_1 < z_s < z_2$ which can be either $z_2 < p^*$ or $z_2 \geq p^*$. However, without further assumptions, we cannot determine the conditions under which this occurs. For illustration, let's take the derivative of (21) with respect to z_{t+1} and evaluate it at $z_{t+1} = z_s$. We obtain the following expression:

$$f'(z_s) = \frac{1}{1+i} \left[\frac{\alpha(1-\sigma+\sigma\chi)}{\chi} \{L'(z_s)z_s + L(z_s)\} + 1 \right] \quad (29)$$

As $L'(z_s)$ is not explicitly defined here, we are unable to establish the conditions under which the standard condition of cycles, $f'(z_s) < -1$, would hold under the general bilateral trading mechanism.

We can show the existence of an endogenous cycle without relying on the standard treatment of $f'(\cdot) < -1$. To establish a sufficient condition for an endogenous cycle, consider a two-period cycle with $z_1 < z_s < p^* \leq z_2$. Since $z_2 \geq p^*$, this cycle satisfies

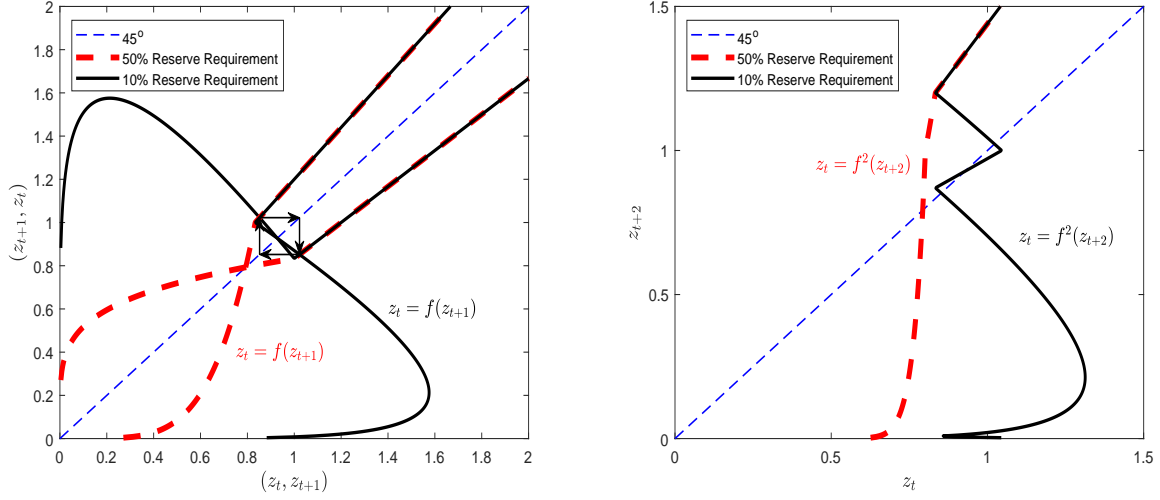

Figure 2: A Two-period Cycle under Fractional Reserve Banking

$z_1 = \frac{z_2}{1+i} < z_s < p^*$, where z_1 solves

$$L(z_1) = \frac{(1+i)^2 - 1}{\alpha(1 - \sigma + \sigma\chi)}\chi.$$

It is straightforward to show that $z_1 < z_s$ because $L'(\cdot) < 0$, and z_s solves (28). By checking the condition $z_2 = z_1(1+i) > p^*$, we can derive the condition under which the economy exhibits a two-period cycle that satisfies $z_1 < z_s < p^* \leq z_2$.

Proposition 2 (Two-period Monetary Cycle). *There exists a two-period cycle with $z_1 < z_s < p^* \leq z_2$ if $\chi \in (0, \bar{\chi}_m]$, where*

$$\bar{\chi}_m \equiv \frac{(1 - \sigma)\alpha L\left(\frac{p^*}{1+i}\right)}{(1+i)^2 - 1 - \sigma\alpha L\left(\frac{p^*}{1+i}\right)}.$$

When this type of two-period cycle exists, lowering χ increases the difference between peak and trough, $z_2 - z_1$.

Proof. See Appendix A. ■

Proposition 2 shows that, under the general trading mechanism, lowering the reserve requirement can induce a two-period cycle and increase the volatility of the real balances. Figure 2 shows an example of this case. By lowering χ , $f(\cdot)$ is more likely to have the backward bending feature. With low χ , if the liquidity premium dominates the storage value, we can have an endogenous cycle.

Now, let's introduce some additional assumptions to determine the condition for χ such that $f'(z_s) < -1$. Consider a special case where $-qu''(q)/u'(q) = \eta$, $c(q) = q$, and the buyer makes a take-it-or-leave-it (TIOLI) offer. In this case, as $L(z_s) = u'(q) - 1$ and $L'(z_s)z_s = z_s u''(z_s) = -\eta u'(z_s)$, we can rewrite (29) as follows:

$$f'(z_s) = \frac{1}{1+i} \left\{ \frac{1-\sigma+\sigma\chi}{\chi} \alpha [u'(z_s)(1-\eta) - 1] + 1 \right\} < -1 \quad (30)$$

where $u'(z_s) = 1 + \frac{i\chi}{\alpha(1-\sigma+\sigma\chi)}$. Solving (30) for χ yields the following proposition.

Proposition 3. *Assume $-qu''(q)/u'(q) = \eta$, $c(q) = q$, and the buyer makes take-it-or-leave-it offer to the seller. If $\chi \in (0, \chi_m)$, where*

$$\chi_m \equiv \frac{\alpha\eta(1-\sigma)}{\eta(1-\alpha\sigma) + (2-\eta)(1+i)}, \quad (31)$$

then $f'(z_s) < -1$.

Proof. See Appendix A. ■

Since $\chi < \chi_m$ implies $f'(z_s) < -1$, following the standard textbook method (see Azariadis, 1993), we can show that if $\chi < \chi_m$, there exists a two-period cycle with $z_1 < z_s < z_2$. Whereas (31) is written in terms of χ , this condition can be written in terms of i , as follows:

$$0 < i < \frac{\eta[\alpha(1-\sigma) - \chi(1-\alpha\sigma)]}{\chi(2-\eta)} \quad (32)$$

The role of i on cycles depends on η . By (32), if $\eta < 2$, lowering either χ or i can induce a cycle. If $2/(\alpha\sigma) > \eta > 2$, χ_m is negative when $i > \frac{\eta\alpha\sigma-2}{2-\eta}$ and positive when $i < \frac{\eta\alpha\sigma-2}{2-\eta}$. In this case, setting i higher than $\frac{\eta\alpha\sigma-2}{2-\eta}$ eliminates cyclic equilibria. If $\eta \geq 2/(\alpha\sigma)$, χ_m is negative for all i , implying the cycle does not exist. When $\eta = 2$, χ_m is constant, implying that the i has no effect on the cycle in this case.

In addition to the conditions for a two-period cycle, the next result provides the condition for a three-period cycle under the general trading mechanism. The existence of three period-cycles implies cycles of all orders as well as chaotic dynamics (see Sharkovskii, 1964 and Li and Yorke, 1975).

Proposition 4 (Three-period Monetary Cycle and Chaos). *A three-period cycle with $z_1 < z_2 < p^* < z_3$ does not exist. There exists a three-period cycle with $z_1 < p^* <$*

Figure 3: A Three-period Cycle under Fractional Reserve Banking

$z_2 < z_3$ if $\chi \in (0, \hat{\chi}_m]$, where

$$\hat{\chi}_m \equiv \frac{(1 - \sigma)\alpha L \left(\frac{p^*}{1+i} \right)}{(1 + i)^3 - 1 - \sigma\alpha L \left(\frac{p^*}{1+i} \right)}.$$

When this type of three-period cycle exists, lowering χ increases the difference between peak and trough, $z_3 - z_1$.

Proof. See Appendix A. ■

The following corollary is a direct result from Proposition 4.

Corollary 1 (Binding Liquidity Constraint). *In any n -period cycle, the liquidity constraint binds, $z_t < p^*$, at least one periodic point over the cycle.*

Proof. See Appendix A. ■

The model can also generate sunspot cycles. Consider a Markov sunspot variable $S_t \in \{1, 2\}$. This sunspot variable is not related to fundamentals but may affect equilibrium. Let $\Pr(S_{t+1} = 1|S_t = 1) = \zeta_1$ and $\Pr(S_{t+1} = 2|S_t = 2) = \zeta_2$. The sunspot is realized in the FM. Let W_t^S be the CM value function in state S in period t , then

$$\begin{aligned} W_t^S(m_t, d_t, \ell_t) &= \max_{X_t, H_t, \hat{m}_{t+1}} U(X_t) - H_t + \beta [\zeta_s G_{t+1}^S(\hat{m}_{t+1}) + (1 - \zeta_s) G_{t+1}^{-S}(\hat{m}_{t+1})] \\ \text{s.t. } \phi_t^S \hat{m}_{t+1} + X_t &= H_t + T_t + \phi_t^S m_t + (1 + i_{d,t}) \phi_t^S d_t - (1 + i_{l,t}) \phi_t^S \ell_t. \end{aligned}$$

The FOC can be written as

$$-\phi_t^S + \beta\zeta_s G_{t+1}'^S(\hat{m}_{t+1}) + \beta(1 - \zeta_s)G_{t+1}'^{-S}(\hat{m}_{t+1}) = 0. \quad (33)$$

Solving the FM problem results in

$$G_{t+1}'^S(m_{t+1}^S) = \phi_{t+1}^S \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_{t+1}^S) + 1 \right]. \quad (34)$$

We substitute (34) into (33) and use the money market clearing condition $m_{t+1} = M_{t+1}$ to get the Euler equation.

$$\phi_t^S = \beta\zeta_s \phi_{t+1}^S \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_{t+1}^S) + 1 \right] + \beta(1 - \zeta_s) \phi_{t+1}^{-S} \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_{t+1}^{-S}) + 1 \right].$$

where $z_{t+1}^S = \phi_{t+1}^S M_{t+1} (1 - \sigma + \sigma\chi) / \sigma\chi$. Then multiply both sides of the Euler equation by $M_t (1 - \sigma + \sigma\chi) / \sigma\chi$ to reduce the equilibrium condition into one difference equation of real balances z_{t+1}^S :

$$\begin{aligned} z_t^S &= \frac{\zeta_s z_{t+1}^S}{1+i} \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_{t+1}^S) + 1 \right] + \frac{(1 - \zeta_s) z_{t+1}^{-S}}{1+i} \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_{t+1}^{-S}) + 1 \right] \\ &= \zeta_s f(z_{t+1}^S) + (1 - \zeta_s) f(z_{t+1}^{-S}). \end{aligned} \quad (35)$$

We define a sunspot equilibrium as follows:

Definition 2 (Proper Sunspot Equilibrium). *A proper sunspot equilibrium consists of the sequences of real balances $\{z_t^S\}_{t=0, S=1,2}^\infty$ and probabilities (ζ_1, ζ_2) , solving (35) for all t .*

Consider stationary sunspot equilibria with $z^1 < z^2$ that only depend on the state, not the time. The liquidity constraint is binding in state $S = 1$. By the standard approach (see again Azariadis, 1993 for the textbook treatment), the condition for two-period cycles is also sufficient and necessary for two-state sunspot equilibrium. If $f'(z_s) < -1$ or $\chi < \bar{\chi}_m$, there exists $(\zeta_1, \zeta_2) \in (0, 1)^2$, $\zeta_1 + \zeta_2 < 1$, such that the economy has a proper sunspot equilibrium in the neighborhood of z_s .

Proposition 5 (Stationary Sunspot Equilibria). *The stationary sunspot equilibrium exists if either $\chi < \chi_m$ or $f'(z_s) < -1$.*

Proof. See Appendix A. ■

Figure 4: Self-Fulfilling Bubble and Burst Equilibrium

In addition to the deterministic and stochastic cycles, the model also features the equilibria where real balance increases above the steady-state until certain time, T , and crashes to zero. Consider a sequence of real balances $\{z_t\}_{t=0}^{\infty}$ with $z_T \equiv \max\{z_t\}_{t=0}^{\infty} > z_s$ (bubble) that crashes to 0 (burst) as $t \rightarrow \infty$, where $T \geq 1$ and $z_T > z_0$. We refer to this equilibrium as a self-fulfilling bubble and burst equilibrium:

Definition 3 (Self-Fulfilling Bubble and Burst Equilibrium). *For initial real balance $z_0 > 0$, a self-fulfilling bubble and burst equilibrium is a sequence of $\{z_t\}_{t=0}^{\infty}$ satisfying (27) and $0 < z_s < z_T$, $\lim_{t \rightarrow \infty} z_t = 0$ where $z_T = \max\{z_t\}_{t=0}^{\infty}$ with $T \geq 1$.*

Figure 4 illustrates an example. It starts at z_0 , which is lower than z_s , and then increases, surpassing z_s , repeatedly rising until it reaches z_6 . Afterward, it crashes and eventually converges to 0. The next step is to examine the conditions under which this type of equilibrium can occur. When $z_s > \bar{z}$, where \bar{z} satisfies $f'(\bar{z}) = 0$, multiple equilibria exist. This implies that solving $z_t = f(z_{t+1})$ given z_t yields multiple solutions for z_{t+1} . If $f(\bar{z}) \geq q^*$, the self-fulfilling bubble and burst equilibrium exists. Assuming $-qu''(q)/u'(q) = \eta$, $c(q) = q$, and a buyer makes a TIOLI offer to the seller, Proposition 6 shows that lowering the reserve requirement can induce this type of equilibrium.

Proposition 6 (Existence of Self-Fulfilling Bubble and Burst Equilibria). *Assume $-qu''(q)/u'(q) = \eta$, $c(q) = q$, and the buyer makes take-it-or-leave-it offer to*

the seller. There exist a self-fulfilling bubble and burst equilibrium, if

$$0 < \chi < \min \left\{ \frac{(1 - \sigma)\alpha\eta(1 + i)}{(1 - \eta)^2 q^* + (1 + i)[(1 - \eta)(3 + i - \eta) - \alpha\sigma\eta]}, \frac{\alpha\eta(1 - \sigma)}{1 + i - \eta(i + \alpha\sigma)} \right\}$$

Proof. See Appendix A. ■

During the bubble, the return on money is equal to $1/(1 + i)$, and liquidity is abundant. However, the real balances cannot continue to increase indefinitely otherwise it would violate the transversality condition. The real balances rises until a certain point, at which the economy crashes, moving toward a non-monetary equilibrium. The timing of these crashes is indeterminate.

4 Money and Unsecured Credit

Consider an alternative payment instrument in the DM - unsecured credit. The buyer can pay for DM goods using unsecured credit that will be redeemed to the seller in the following CM and she can borrow up to her debt limit, \bar{b}_t . For simplicity, I assume that the buyer makes a TIOLI offer to the seller in the DM, which means the buyer maximizes her surplus subject to the seller's participation constraint. The DM cost function is $c(q) = q$. Suppose the buyer has issued b_t units of unsecured debt in the previous DM. The CM value function is

$$\begin{aligned} W_t(m_t, d_t, \ell_t, -b_t) &= \max_{X_t, H_t, \hat{m}_{t+1}} U(X_t) - H_t + \beta G_{t+1}(\hat{m}_{t+1}) \\ \text{s.t. } \phi_t \hat{m}_{t+1} + X_t &= H_t + T_t + \phi_t m_t + (1 + i_{d,t})\phi_t d_t - (1 + i_{l,t})\phi_t \ell_t - b_t, \end{aligned} \tag{36}$$

which is the same as before except that the agent needs to pay or collect the debt. The agent's FM problem is identical to the previous section. Then, $1 - \sigma$ fraction of agents will deposit \hat{m}_{t+1} , and σ fraction of agents will borrow loan from the bank. The DM value function is

$$V_t^b(m_t + \ell_t, 0, \ell_t) = \alpha[u(q_t) - q_t] + W_t(m_t + \ell_t, 0, \ell_t, 0),$$

where $q_t = \min\{q^*, \bar{b}_t + \phi_t(m_t + \ell_t)\}$. Given \bar{b}_t , solving equilibrium yields

$$z_t = \begin{cases} \frac{z_{t+1}}{1+i} \left\{ \frac{1-\sigma+\sigma\chi}{\chi} \alpha [u'(z_{t+1} + \bar{b}_{t+1}) - 1] + 1 \right\} & \text{if } z_{t+1} + \bar{b}_{t+1} < q^* \\ \frac{z_{t+1}}{1+i} & \text{if } z_{t+1} + \bar{b}_{t+1} \geq q^*, \end{cases} \quad (37)$$

where $z_{t+1} = (1 - \sigma + \sigma\chi)\phi_{t+1}M_{t+1}/(\sigma\chi)$.

Next, I am going to endogenize the debt limit. The buyer cannot commit to pay back the debt. If the buyer reneges she is captured with probability μ . The punishment for a defaulter is permanent exclusion from the DM trade but she can still produce for herself in the CM. The value of autarky is $\underline{W}(0, 0, 0, 0) = [U(X^*) - X^* + T]/(1 - \beta)$. The incentive condition for voluntary repayment is

$$\underbrace{-b_t + W_t(m_t, d_t, \ell_t, 0)}_{\text{value of honoring debts}} \geq \underbrace{(1 - \mu)W_t(m_t, d_t, \ell_t, 0) + \mu\underline{W}(m_t, d_t, \ell_t, 0)}_{\text{value of not honoring debts}}.$$

One can write the debt limit \bar{b}_t as $b_t \leq \bar{b}_t \equiv \mu W_t(0, 0, 0, 0) - \mu\underline{W}(0, 0, 0, 0)$. Recall the CM value function. Using the solution of FM, we can rewrite the buyer's CM value function as

$$\begin{aligned} W_t(0, 0, 0, 0) &= U(X^*) - X^* + T_t + \beta W_{t+1}(0, 0, 0, 0) \\ &\quad + \max_{\hat{m}_{t+1}} \{-\phi_t \hat{m}_{t+1} + \beta \alpha \sigma [u(q_{t+1}) - q_{t+1}] + \beta \phi_{t+1} \hat{m}_{t+1}\}, \end{aligned}$$

where $q_{t+1} = \min\{q^*, z_{t+1} + \bar{b}_{t+1}\}$. Substituting $W_t(0, 0, 0, 0) = \bar{b}_t/\mu + \underline{W}(0, 0, 0, 0)$ and $\hat{m}_{t+1} = M_{t+1}$ yields

$$\frac{\bar{b}_t}{\mu} = -\phi_t M_{t+1} + \beta \alpha \sigma [u(z_{t+1} + \bar{b}_{t+1}) - z_{t+1} - \bar{b}_{t+1}] + \frac{\beta \bar{b}_{t+1}}{\mu} + \beta \phi_{t+1} M_{t+1},$$

where M_{t+1} and z_{t+1} solve (37). Rearranging terms yields

$$\bar{b}_t = \begin{cases} \beta \bar{b}_{t+1} + \frac{\chi \mu \sigma [-\gamma z_t + \beta z_{t+1}]}{1 - \sigma + \sigma\chi} + \beta \alpha \mu \sigma S(z_{t+1} + \bar{b}_{t+1}) & \text{if } z_{t+1} + \bar{b}_{t+1} < q^* \\ \beta \bar{b}_{t+1} + \frac{\chi \mu \sigma [-\gamma z_t + \beta z_{t+1}]}{1 - \sigma + \sigma\chi} + \beta \alpha \mu \sigma S(q^*) & \text{if } z_{t+1} + \bar{b}_{t+1} \geq q^*, \end{cases} \quad (38)$$

where $S(z_{t+1} + \bar{b}_{t+1}) \equiv [u(z_{t+1} + \bar{b}_{t+1}) - z_{t+1} - \bar{b}_{t+1}]$ is the buyer's trade surplus. The equilibrium can be collapsed into a dynamic system satisfying (37)-(38).

In the stationary equilibrium, (37) becomes

$$-\frac{i\chi}{\alpha(1-\sigma+\sigma\chi)} + u'(q) - 1 \leq 0, = \text{ if } z > 0 \quad (39)$$

and (38) becomes

$$(1-\beta)\bar{b} = \begin{cases} \frac{\chi\mu\sigma[\beta-\gamma]z}{1-\sigma+\sigma\chi} + \beta\alpha\mu\sigma[u(z+\bar{b}) - z - \bar{b}] & \text{if } z + \bar{b} < q^* \\ \frac{\chi\mu\sigma[\beta-\gamma]z}{1-\sigma+\sigma\chi} + \beta\alpha\mu\sigma[u(q^*) - q^*] & \text{if } z + \bar{b} \geq q^*, \end{cases} \quad (40)$$

where $q = \min\{z + \bar{b}, q^*\}$. The stationary equilibrium solves the above two equations, and it falls into one of the three cases: the pure money equilibrium, the pure credit equilibrium, and the money-credit equilibrium. First, if no one can capture the buyer after she reneges, $\mu = 0$, the unsecured credit is not feasible, $\bar{b} = 0$. In this case, the equilibrium will be the pure money equilibrium. Second, when \bar{b} solving (40) satisfies $u'(\bar{b}) < i\chi/[\alpha(1-\sigma+\sigma\chi)]$ then money is not valued, $z = 0$. We have the pure credit equilibrium in this case. Third, if solutions of (39)-(40), (z, \bar{b}) are strictly positive then we have the money-credit equilibrium.

The debt limit at the stationary equilibrium, \bar{b} , is a fixed point satisfying $\bar{b} = \Omega(\bar{b})$ where

$$\Omega(\bar{b}) = \begin{cases} \frac{\mu\sigma\alpha}{\rho}[u(\tilde{q}) - \tilde{q}] - \frac{i\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)}(\tilde{q} - \bar{b}) & \text{if } \tilde{q} > \bar{b} \geq 0 \\ \frac{\mu\sigma\alpha}{\rho}[u(\bar{b}) - \bar{b}] & \text{if } q^* > \bar{b} \geq \tilde{q} \\ \frac{\mu\sigma\alpha}{\rho}[u(q^*) - q^*] & \text{if } \bar{b} \geq q^* \end{cases} \quad (41)$$

where \tilde{q} solves $u'(\tilde{q}) = 1 + i\chi/[\alpha(1-\sigma+\sigma\chi)]$ and $\rho \equiv 1/\beta - 1$. The DM consumption q_s is determined by $q_s = \min\{q^*, \max\{\tilde{q}, \bar{b}\}\}$. Money and credit coexist if and only if $0 < \bar{b} < \tilde{q}$, which holds when $0 < \mu < \min\{1, \tilde{\mu}\}$, where

$$\tilde{\mu} \equiv \frac{\rho(1-\sigma+\sigma\chi)}{\alpha\sigma[u(\tilde{q})/\tilde{q} - 1](1-\sigma+\sigma\chi) - 2i\sigma\chi}.$$

The DM consumption is decreasing in i in the stationary monetary equilibrium.

Consider the dynamics of equilibria where money and credit coexist. I claim the main results from Section 3 - lowering the reserve requirement can induce endogenous

cycles - still hold even after unsecured credit is introduced. It is clear that the standard treatment $f'(z_s) < -1$ from [Azariadis \(1993\)](#) cannot be used here because now the equilibrium is consist of system of equations. Instead, I apply the approach used in [Proposition 2](#) and [4](#). For compact notation, let $\iota \equiv \max\{i, \rho\}$ and $w_j \equiv z_j + \bar{b}_j$. The following proposition establishes the conditions for a two-period cycle, a three-period cycle, and chaotic dynamics.

Proposition 7 (Monetary Cycles with Unsecured Credit). *There exists a two-period cycle of money and credit with $w_1 < q^* < w_2$ if $\chi \in (0, \chi_c]$, where*

$$\chi_c \equiv \frac{(1 - \sigma)\alpha \left[u' \left(\frac{q^*}{1+\iota} \right) - 1 \right]}{(1 + i)^2 - 1 - \sigma\alpha \left[u' \left(\frac{q^*}{1+\iota} \right) - 1 \right]}.$$

There exists a three-period cycle of money and credit with $w_1 < q^ < w_2 < w_3$, if $\chi \in (0, \hat{\chi}_c]$, where*

$$\hat{\chi}_c \equiv \frac{(1 - \sigma)\alpha \left[u' \left(\frac{q^*}{1+\iota} \right) - 1 \right]}{(1 + i)^3 - 1 - \sigma\alpha \left[u' \left(\frac{q^*}{1+\iota} \right) - 1 \right]}.$$

Proof. See [Appendix A](#). ■

5 Empirical Evaluation: Inside Money Volatility

In the previous sections, the theoretical results show that lowering the required reserve ratio can induce instability. To evaluate the model prediction, I examine whether the required reserve ratio is associated with the cyclical volatility of the real balance of the inside money.

Following [Jaimovich and Siu \(2009\)](#) and [Carvalho and Gabaix \(2013\)](#), I measure the cyclical volatility in quarter t as the standard deviation of a filtered log real total checkable deposit during a 41-quarter (10-year) window centered around quarter t . Total checkable deposits are from the H.6 Money Stock Measures published by the Federal Reserve Board and converted to real value using the Consumer Price Index (CPI). Seasonally adjusted series are used to smooth the seasonal fluctuation. I adopt the Hodrick-Prescott (HP) filter with a 1600 smoothing parameter as standard. To construct an annual series, quarterly observations are averaged for each year. The sample period is from 1960:I to 2018:IV. To check whether the results are sensitive to different measures of the price level, I also use the core CPI, the Personal Consumption

Table 1: Effect of Required Reserve Ratio

Note: For (1), (3), (5) and (7), OLS estimates are reported, and Newey-West standard errors with lag 1 are reported in parentheses. For (2), (4), (6), and (8), first-stage long-run variance estimations for CCR are based on the quadratic spectral kernel and Bayesian information criterion. The bandwidth selection is based on Newey-West fixed lag, $4 \times (T/100)^{2/9}$; χ denotes the required reserve ratio, **ffr** denotes federal funds rates and σ_t^{Roll} denotes the cyclical volatility of real inside money balances. ***, **, and * denotes significance at the 1, 5, and 10 percent levels, respectively.

Expenditures (PCE), and the core PCE to transform the total checkable deposit into real value.

To compute the required reserve ratios, I divide the required reserves by total checkable deposits instead of using the official legal reserve requirement. The reason for this approach is the following. The legal reserve requirement for demand deposits was 10% from April 2, 1992, to March 25, 2020. However, the Federal Reserve imposed different reserve requirements depending on the size of a bank's liabilities. For example, from December 29, 2011, to December 26, 2012, the Fed had a reserve requirement exemption for liabilities up to \$11.5 million. For liabilities between \$11.5 million and \$71.0 million, the Fed imposed a 3% reserve requirement. These criteria have changed over time. On December 27, 2012, the Fed increased the exemption threshold to \$12.4 million and raised the low reserve tranche from \$71.0 million to \$79.5 million. During 1992:Q1-2019:Q4, there were 27 changes in these thresholds. Dividing the required reserves by total checkable deposits allows us to track these changes as well.

To examine whether there is an association, I regress the required reserve ratio on the cyclical volatility of the inside money real balance. Column (1) of Table 1 reports its

$\Delta \sigma_t^{Roll}$	(PCE)	-29.780***	-4.415**	-3.786*
$\Delta \sigma_t^{Roll}$	(Core PCE)	-29.485***	-4.364**	-3.618*

Note: **ffr** denotes federal funds rates, χ denotes required reserve ratio, and σ_t^{Roll} denotes cyclical volatility of real inside money balances. ***, **, and * denotes significance at the 1, 5, and 10 percent levels, respectively.

regression estimates with Newey-West standard errors. The estimates show a negative relationship between the cyclical volatility of the real inside money balance and the required reserve ratio with statistically significant regression coefficients. However, this result can be driven by a spurious regression. Table 2 provides unit root test results for the federal funds rate, the required reserve ratio, and the cyclical volatility of inside money. Both augmented Dickey-Fuller tests and Phillips-Perron tests fail to reject the null hypotheses of unit roots for these series, whereas they reject the null hypotheses of unit roots at their first differences. In addition to that, the Johansen cointegration test in Column (1), suggests that there is no cointegration relationship between two variables. So it is hard to rule out that Column (1)'s results are driven by a spurious regression.

To overcome this issue, I adopt the cointegrating regression with an additional variable, the federal funds rate. Column (2) of Table 1 provides Johansen cointegration test results for the federal funds rate, the required reserves, and the cyclical volatility of inside money. The trace test suggests a cointegration relationship among these three variables, which is consistent with the theoretical result: The instability depends on the reserve requirement and the interest rate. With the cointegration relationship, we may not have to worry about a spurious relationship. Column (2) of Table 1 reports the

estimates for the cointegrating relationship. Because of the potential bias from long-run variance, I estimate a canonical cointegrating regression (CCR). The estimates suggest a negative association between the required reserves, and the cyclical volatility of inside money, and the coefficients are statistically significant with a sizeable level.

To check the sensitivity of the results, I redo all the analyses using the core CPI, the Personal Consumption Expenditures (PCE), and the core PCE to transform the total checkable deposit into real value. Columns (3), (5), and (7) of Table 1 regress required reserve ratio on the inside money volatility and report its Newey-West standard errors. They also report the trace test statistics of Johansen cointegration test between these two variables. The results are consistent with the benchmark case in Column (1). Columns (4), (6), and (8) of Table 1 report CCR estimates regressing the required reserve ratio and federal funds rate on the inside money volatility and the trace test statistics of Johansen cointegration test between these three variables. All the results are consistent with the benchmark case in Column (2).

Appendix B includes more sensitivity analyses: (1) Using quarterly series instead of annual series; (2) Using time series before 2008; (3) Using alternative data of M1: M1 adjusted for retail sweeps; (4) Using another alternative data of M1 proposed by [Lucas and Nicolini \(2015\)](#). All the results are not sensitive with respect to different frequencies, time periods, and alternative data.

6 Calibrated Examples

6.1 Parameters and Targets

In this section, I calibrate the model using U.S. data. I calibrate both the model without unsecured credit and the model with unsecured credit. First, assuming there is no unsecured credit, I calibrate the model without unsecured credit, which will be referred to as Model 1 throughout this section. In addition to Model 1, I also calibrate the model with unsecured credit, referred to as Model 2. For monetary aggregates, I use M1 adjusted for retail sweep accounts as in [Aruoba, Waller and Wright \(2011\)](#) and [Venkateswaran and Wright \(2014\)](#). Following to [Krueger and Perri \(2006\)](#), revolving consumer credit series are used as unsecured credit.

I set the discount rate $\beta = 0.9709$ to match the real annual interest rate of 3%. Using the average required reserve to deposit ratio for 1980Q1-2008Q4, the benchmark reserve requirement is set to 7.77%. The benchmark value for i is set to 0.0564 as the

Figure 5: Money Demand

average annualized nominal interest rate is 5.64%. The matching function in the DM is $\mathcal{M}(\mathcal{B}, \mathcal{S}) = \frac{\mathcal{B}\mathcal{S}}{\mathcal{B} + \mathcal{S}}$, where \mathcal{B} and \mathcal{S} denotes the measure of buyers and sellers, respectively. This implies $\alpha = \mathcal{M}(\sigma, 1 - \sigma)/\sigma = (1 - \sigma)$ and $\alpha_s = \mathcal{M}(\sigma, 1 - \sigma)/(1 - \sigma) = \sigma$. The fraction of buyer is set to $\sigma = 0.5$ for a normalization. The utility functions for the parameterization are

$$U(X) = B \log(X), \quad u(q) = \frac{Cq^{1-\eta}}{1-\eta}$$

implying $X^* = B$ and the DM cost function is given as $c(q) = q$. Assume the buyer makes a take-it-or-leave-it offer to the seller in the DM trade, implying $\lambda(q) = Cq^{-\eta} - 1$.

This section focuses on the equilibrium where $X > 0$ which requires $U(X) - X > 0$. To guarantee $U(X) - X > 0$, we need to have $\log(B) > 1$ since $B = X^*$. Otherwise, the CM consumption is zero, $X = 0$. For normalization, I set $B = 3$. The parameters (C, η) are set to match the money demand relationship. In the model, the money demand relationship is given by real balances of money as a fraction of output

$$Z \equiv \frac{z}{y} = \frac{z}{B + \sigma \alpha q}$$

where y is the real output of the economy and elasticity of z/y with respect to i

$$\frac{\partial \log(Z)}{\partial \log(i)} = \frac{i}{Z} \frac{\partial Z}{\partial i}.$$

Specifically, the parameter C is set to match the average money stock to GDP ratio,

Table 3: Model Parametrization

	Data	Model 1	Model 2
		No Credit, $\mu = 0$	With Credit, $\mu > 0$
Parameters			
DM utility level, C		0.8488	1.0658
DM utility curvature, η		0.2312	0.5436
Monitoring probability, μ		-	0.0547
Targets			
avg. z/y	0.1473	0.1475	0.1482
elasticity of z/y wrt i	-0.0661	-0.0661	-0.0661
avg. $\sigma\alpha b/y$	0.0466	-	0.0464

which is 0.1473, and the parameter η is set to match the elasticity of z/y with respect to i . The target elasticity is estimated using the following regression:

$$\log(Z_t) = \beta_0 + \beta_1 \log(i_t) + \varepsilon_t$$

The estimated elasticity is $\beta_1 = -0.0661$. In Model 2, agents can use unsecured credit in DM trade, and the monitoring probability μ is set to match the amount of unsecured credit in the economy as a fraction of output, which is 0.0466. Its model counterpart is $\sigma\alpha b/y$. The closed-form solutions of targets from the models can be found in Appendix C. Figure 5 shows the fitted money demand and Table 3 shows the calibrated parameters and the target moments.

6.2 Model Implied Thresholds

Given the parameterization from the previous section, this section examines whether the conditions of endogenous cycles hold or not. The left panel of Figure 6 shows the thresholds for a two-period cycle χ_m , and $\bar{\chi}_m$, and the threshold for a three-period cycle and chaotic dynamics $\hat{\chi}_m$ under different i in Model 1. The thresholds for two-period cycles χ_m and $\bar{\chi}_m$ are almost the same and vary around 0.026 to 0.030. The threshold for a three-period cycle $\hat{\chi}_m$ varies from 0.016 to 0.020. The region A_1 denotes the area satisfying $\chi > \chi_m$ which means that there is no cycle. The region A_2 denotes the area satisfying $\chi_m > \chi > \hat{\chi}_m$. In the A_2 region, there are two-period cycles but higher order cycles do not exist. The region A_3 denotes the area satisfying $\chi < \hat{\chi}_m$ which implies there exist higher-order cycles and chaotic dynamics. In Model 1, both of the model-implied thresholds are decreasing in i . Lowering i and χ both can result in cyclic equilibria.

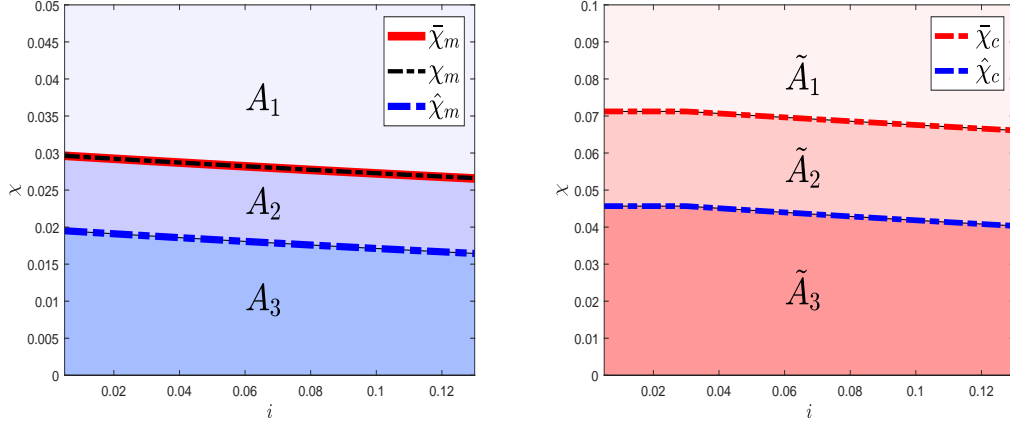

Figure 6: Calibrated Examples I

Figure 7: Calibrated Examples II

The right panel of Figure 6 shows the thresholds for the two-period cycles χ_c and three-period and chaotic dynamics $\hat{\chi}_c$ in Model 2. The thresholds for cycles in Model 2 are much lower than the thresholds for cycles in Model 1 and increasing in i . χ_c vary from 0.065 to 0.071 $\hat{\chi}_c$ vary from 0.039 to 0.046

The region \tilde{A}_1 , \tilde{A}_2 , and \tilde{A}_3 denotes the area satisfying $\chi > \chi_c$, $\chi_c > \chi > \hat{\chi}_c$, and $\chi < \hat{\chi}_c$, respectively.

Figure 7 plots the model-implied thresholds over time. The left panel of Figure 7 shows that both of χ_m and $\hat{\chi}_m$ are lower than χ . The right panel of Figure 7 plots the model-implied thresholds over time. While both of χ_c and $\hat{\chi}_c$ are higher than χ , they are very close to χ after 2000. This says the economy could exhibit endogenous fluctuations and chaotic dynamics. It implies that the economy may have endogenous cycles as well as sunspot cycles due to fractional reserve banking, which is independent

of the presence of exogenous shocks and changes in fundamentals.

In both models, the endogenous cycle thresholds are not low enough to be ignored, showing that this channel of volatility needs to be considered in addition to economic fluctuations induced by exogenous shocks that disrupt the dynamic system.

6.3 News Shocks

This section studies discrete-time dynamics resulting from news on future changes in monetary policy, following [Gu, Han and Wright \(2019b\)](#) and [Burdett, Trejos and Wright \(2017\)](#). Let the central bank change i permanently, from i_0 to i_T .⁵ Suppose news on changes in the monetary policy at T is announced at time 0. First, consider the dynamics without unsecured credit, i.e., $\mu = 0$.

The permanent change in i from i_0 to i_T implies a shift of equation (27) from $z_t = f_0(z_{t+1}; i_0, \chi_0)$ to $z_t = f_T(z_{t+1}; i_T, \chi_T)$. Let $z_s(i, \chi)$ be a steady state for given monetary policy, (i, χ) . Then, the transition starts in steady state with $z_s(i_0, \chi)$ and ends with $z_s(i_T, \chi)$. This can be solved by backward induction, as follows.

$$z_T = f_T(z_T), \quad z_{T-1} = f_0(z_T), \quad z_{T-2} = f_0(z_{T-1}), \quad \dots \quad z_0 = f_0(z_1)$$

Consider a case with $T = 9$. In Figure 8, we start with a stationary equilibrium with $i = 0.1$. At time 0, it is announced that there will be a permanent change in i to 0.02 at time $T = 9$. The stationary equilibrium with $i = 0.02$ is a terminal condition for this dynamics system. The top-right panel of Figures 8 shows when $\chi = 100$. It jumps and steadily converges to new steady state.

To get a feel for magnitudes, ... Thus news about an upcoming change in i generates significant effects.

Now we introduce unsecured credit, $\mu > 0$. Similar to the previous experiment, the permanent change from i_0 to i_T implies a shift of equations (37) and (38), from $z_t = \Phi_0(z_{t+1}, \bar{b}_{t+1}; i_0, \chi_0)$ and $\bar{b}_t = \Gamma_0(z_{t+1}, \bar{b}_{t+1}; i_0, \chi_0)$ to $z_t = \Phi_T(z_{t+1}, \bar{b}_{t+1}; i_T, \chi_T)$ and $\bar{b}_t = \Gamma_T(z_{t+1}, \bar{b}_{t+1}; i_T, \chi_T)$, respectively. Then, starting in steady state with (z_0, \bar{b}_0) and ending in steady state with (z_T, \bar{b}_T) , the transitional dynamics of the equilibrium with

⁵The permanent change in i implies a permanent change in the rate of monetary expansion, γ , from $\gamma_0 = \beta(1 + i_0)$ to $\gamma_T = \beta(1 + i_T)$.

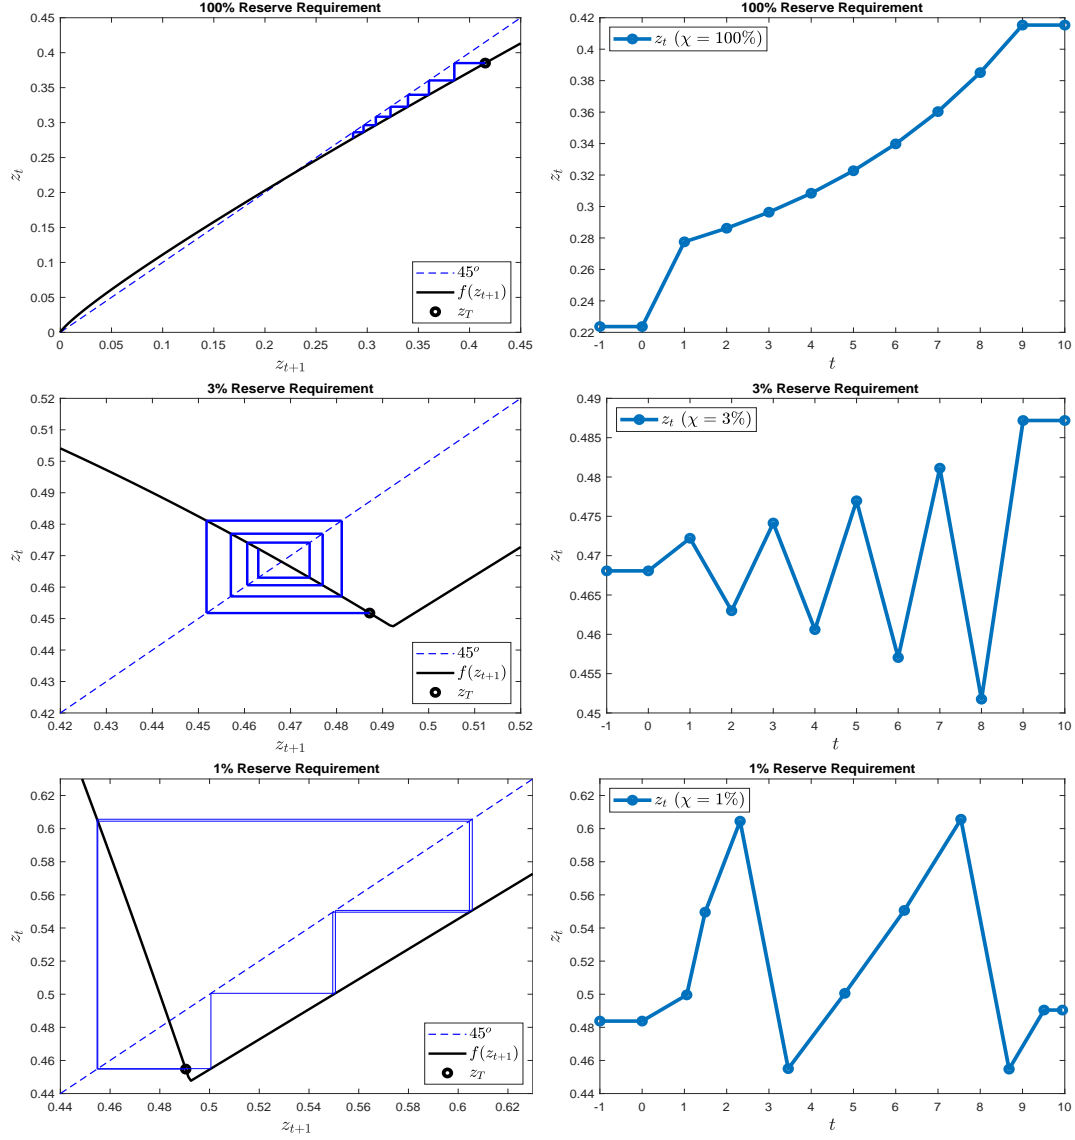

Figure 8: Phase Dynamics and Transition Paths for Known Policy Change: Model 1

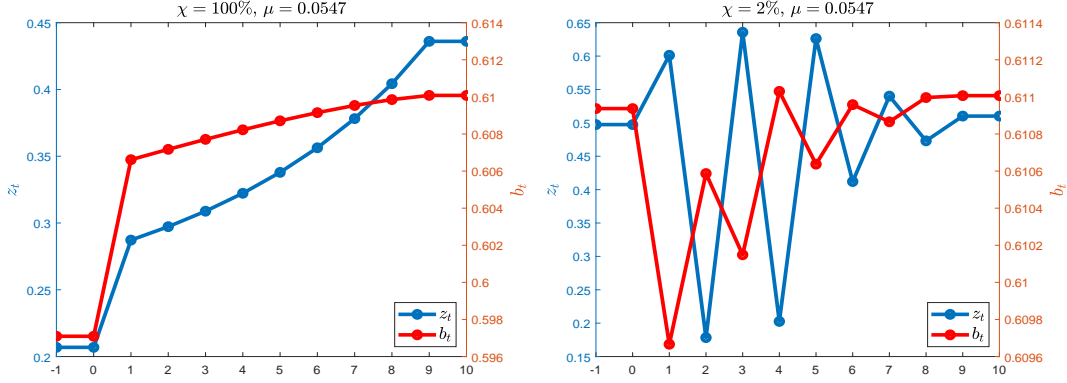

Figure 9: Transition Paths for Known Policy Change: Model 2

unsecured credit also can be solved by backward induction.

$$\begin{aligned}
 z_T &= \Phi_T(z_T, \bar{b}_T), & z_{T-1} &= \Phi_0(z_T, \bar{b}_T), & z_{T-2} &= \Phi_0(z_{T-1}, \bar{b}_{T-1}), & \dots & z_0 = \Phi_0(z_1, \bar{b}_1) \\
 \bar{b}_T &= \Gamma_T(z_T, \bar{b}_T), & \bar{b}_{T-1} &= \Gamma_0(z_T, \bar{b}_T), & \bar{b}_{T-2} &= \Gamma_0(z_{T-1}, \bar{b}_{T-1}), & \dots & \bar{b}_0 = \Gamma_0(z_1, \bar{b}_1)
 \end{aligned}$$

Consider a case with $T = 9$. In Figures 8 and 9, we start with a stationary equilibrium with $i = 0.1$. At time 0, it is announced that there will be a permanent change in i to 0.02 at time $T = 9$. The stationary equilibrium with $i = 0.02$ is a terminal condition for this dynamics system. In both experiments, the real money balance converges to the new equilibrium smoothly when $\chi = 0.12$, but real money balances fluctuates a lot when reserve requirements are very low.

7 Conclusion

The goal of this paper is to examine the (in)stability of fractional reserve banking. To that end, this paper builds a simple monetary model of fractional reserve banking that can capture the conditions for (in)stability under different specifications. Lowering the reserve requirement increases the welfare at the steady state. However, it can induce instability. The baseline model and its extension establish the conditions for endogenous cycles and chaotic dynamics. The model also features stochastic cycles and self-fulfilling boom and burst under explicit conditions. The model shows that fractional reserve banking can endanger stability in the sense that equilibrium is more prone to exhibit cyclic, chaotic, and stochastic dynamics under lower reserve requirements. This is due to the amplified liquidity premium. This result holds in the

extended model with unsecured credit.

This paper also provides some empirical evidence that is consistent with the prediction of the model. I test the association between the required reserves ratio and the real inside money volatility using cointegrating regression. I find a significant negative relationship between the two variables. Both theoretical and empirical evidence find a link between the reserve requirement policy and (in)stability.

Appendix

Appendix A Proofs

Proof of Proposition 1. Recall (28)

$$\chi i = (1 - \sigma + \sigma \chi) \alpha L(z_s) \quad (42)$$

■

Proof of Proposition 2. Let there exists a two-period cycle satisfying $z_1 < z_s < p^* < z_2$. Since $z_2 > p^*$, we have $z_2 = (1 + i)z_1$. Using (27) with $z_1 < p^*$ gives

$$\chi = \frac{(1 - \sigma) \alpha L(z_1)}{(1 + i)^2 - 1 - \sigma \alpha L(z_1)} \quad (43)$$

This two-period cycle should satisfy $z_1 < z_s < p^*$ and $z_2 = (1 + i)z_1 > p^*$. First one can be easily shown using

$$0 = L(p^*) < L(z_s) = \frac{i}{\alpha(1 - \sigma + \sigma \chi)} \chi < \frac{(1 + i)^2 - 1}{\alpha(1 - \sigma + \sigma \chi)} \chi = L(z_1)$$

since we have $L'(\cdot) < 0$. Because $dz_1/d\chi < 0$, the latter one, $z_1 > p^*/(1 + i)$, is held when

$$0 < \chi < \frac{(1 - \sigma) \alpha L\left(\frac{p^*}{1+i}\right)}{(1 + i)^2 - 1 - \sigma \alpha L\left(\frac{p^*}{1+i}\right)}.$$

■

Proof of the Existence of a Two-period Monetary Cycle where $f'(z) < -1$. Let $f^2(z) = f \circ f(z)$. With given the unique steady state, $f(z) > z$ for $z < z_s$ and $f(z) < z$ for $z > z_s$. Because $f(z)$ is linear increasing function for $z > p^*$, there exist a $\tilde{z} > p^*$ s.t $f(\tilde{z}) > p^*$. Since $\tilde{z} > p^*$ and $f(\tilde{z}) < \tilde{z}$, \tilde{z} satisfies $f^2(\tilde{z}) < f(\tilde{z}) < \tilde{z}$. We can write slope of $f^2(z)$ as follows.

$$\frac{\partial f^2(z)}{\partial z} = f'[f(z)]f'(z) = f'(z)f'(z) = [f'(z)]^2$$

which implies $\partial f^2(z)/\partial z > 1$ when $f'(z) < -1$. And it is easy to show $\partial f^2(0)/\partial z > 0$. With given $i > 0$ and $\chi > 0$, there exist a (z_1, z_2) , satisfying $0 < z_1 < z_s < z_2$ which

are fix points for $f^2(z)$

$$\frac{(1+i)^2 - 1}{\alpha(1 - \sigma + \sigma\chi)}\chi = L(z_1), \text{ and } z_2 = (1+i)z_1$$

... shows that lowering the reserve requirement can induce a two-period cycle. We can also check whether it also increases the volatility. Consider the difference between peak and trough $z_2 - z_1 = iz_1$. Since $dz_1/d\chi = \frac{L(z_1)}{L'(z_1)} \left(\frac{1-\sigma}{\chi^2} \right) / \left(\frac{1-\sigma}{\chi} + 1 \right) < 0$, ■

Proof of Proposition 3. When DM trade is based on take-it-or-leave-it offer from buyer to seller with $c(q) = q$ and $-qu''(q)/u' = \eta$, f' can be written as

$$f'(q) = \frac{1}{1+i} \left\{ \frac{1 - \sigma + \sigma\chi}{\chi} \alpha [u''(q)q + u'(q) - 1] + 1 \right\} < -1$$

Using $u''(q)q = -\eta u'(q)$ gives

$$\frac{1 - \sigma + \sigma\chi}{\chi} \alpha [u'(q)(1 - \eta) - 1] + 1 < -(1+i)$$

where $u'(q) = 1 + \frac{i\chi}{\alpha(1-\sigma+\sigma\chi)}$. Substituting $u'(q)$ and rearranging terms give

$$0 < \chi < \frac{\alpha\eta(1 - \sigma)}{\eta(1 - \alpha\sigma) + (2 - \eta)(1 + i)}.$$

■

Proof of Proposition 4. I divide three period cycles into two cases.

Case 1: Let there exists a three-period cycle satisfying $z_1 < z_s < p^* < z_2 < z_3$. Since $z_2, z_3 > p^*$, we have $z_2 = (1+i)z_1$, $z_3 = (1+i)z_2 = (1+i)^2 z_1$. Using (27) with $z_1 < p^*$ gives

$$\chi = \frac{(1 - \sigma)\alpha L(z_1)}{(1+i)^3 - 1 - \sigma\alpha L(z_1)} \quad (44)$$

This three-period cycle should satisfy $z_1 < z_s < p^*$ and $z_2 = (1+i)z_1 > p^*$. First one can be easily shown using

$$0 = L(p^*) < L(z_s) = \frac{i}{\alpha(1 - \sigma + \sigma\chi)}\chi < \frac{(1+i)^3 - 1}{\alpha(1 - \sigma + \sigma\chi)}\chi = L(z_1)$$

since we have $L'(\cdot) < 0$. Because $dz_1/d\chi < 0$, the latter one, $z_1 > p^*/(1+i)$, is held

when

$$0 < \chi < \frac{(1 - \sigma)\alpha L\left(\frac{p^*}{1+i}\right)}{(1+i)^3 - 1 - \sigma\alpha L\left(\frac{p^*}{1+i}\right)}.$$

Case 2: Let there exists a three-period cycle satisfying $z_1 < z_2 < p^* \leq z_3$. Since $z_3 > p^*$, we have $z_3 = z_2(1+i)$ and (z_2, z_1) solves (45)-(46).

$$z_1 = f(z_2) = \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_2) + 1 \right] \frac{z_2}{1+i} \quad (45)$$

$$z_2 \equiv \tilde{f}(z_1) = \left[\frac{1 - \sigma + \sigma\chi}{\chi} \alpha L(z_1) + 1 \right] \frac{z_1}{(1+i)^2}. \quad (46)$$

These functions satisfies $f(x) > x$ for $x < z_s$, $f(x) < x$ for $x > z_s$, $\tilde{f}(x) > x$ for $x < \tilde{z}$

Figure 10: Intersection of $\tilde{f}(z)$ and $f(z)$

and $\tilde{f}(x) < x$ for $x > \tilde{z}$ where \tilde{z} solves $\tilde{z} = \tilde{f}(\tilde{z})$. One can easily show $\tilde{z} < z_s$. Therefore any intersection between $z_1 = f(z_2)$ and $z_2 = \tilde{f}(z_1)$ satisfies $z_1 > z_2$ which contradicts to our initial conjecture $z_1 < z_2$. This implies there is no three-period cycles satisfying $z_1 < z_2 < p^* \leq z_3$. Therefore we can conclude that a three-period cycle exist when

$$0 < \chi < \frac{(1 - \sigma)\alpha L\left(\frac{p^*}{1+i}\right)}{(1+i)^3 - 1 - \sigma\alpha L\left(\frac{p^*}{1+i}\right)}.$$

The existence of a three-cycle implies the existence of cycles of all orders and chaotic dynamics by the Sarkovskii theorem (Sharkovskii, 1964) and the Li-Yorke theorem (Li and Yorke, 1975). ■

Proof of Corollary 1: Proposition 4 shows that at least one periodic point satisfies

$z_t < z_s < p^*$ in 3- period cycles. Two period cycles satisfies $z_1 < z_s < z_2$ also implies at least one periodic point satisfies $z_t < z_s < p^*$ in 2-period cycles since $z_1 < z_s < p^*$. This result holds for any n -periodic cycles. Let $z_1 < z_2 < \dots < z_n$ be the periodic points of a n -cycle. Suppose $z_j > z_s$ for all $j = 1, 2, \dots, n$. By the definition of a n -period cycle, $z_1 = f(z_n) < z_n$ since $f(z) < z$ for $z > z_s$.

$$z_n = f(z_{n-1}) < z_{n-1} = f(z_{n-2}) < z_{n-2} \dots < z_1.$$

which shows the contradiction implying at least one periodic point satisfies $z_t < z_s < p^*$. ■

Proof of Proposition 5. By definition, if there exists (ζ_1, ζ_2) satisfying

$$z^1 = \zeta_1 f(z^1) + (1 - \zeta_1) f(z^2) \tag{47}$$

$$z^2 = (1 - \zeta_2) f(z^1) + \zeta_2 f(z^2) \tag{48}$$

with $\zeta_1, \zeta_2 < 1$, then there exists a proper sunspot equilibrium. Because z^1 and z^2 are weighted averages of $f(z^1)$ and $f(z^2)$, where $f(z^1) > z^1$ and $f(z^2) < z^2$, by the uniqueness of the positive steady state, necessary and sufficient conditions for (47) and (48) are

$$f(z^2) < z_1 < f(z^1) \text{ and } f(z^2) < z_2 < f(z^1).$$

Since $z^1 < z^2$, above conditions are reduce to

$$z^2 < f(z^1) \text{ and } z^1 > f(z^2). \tag{49}$$

When $\chi < \chi_m$, there exists (z^1, z^2) that satisfies (49). Rewrite (47) and (48) as

$$\zeta_1 + \zeta_2 = \frac{z^1 - f(z^2) - z^2 + f(z^1)}{f(z^1) - f(z^2)} = \frac{z^1 - z^2}{f(z^1) - f(z^2)} + 1 < 1 \tag{50}$$

since $z^2 < z^1$ and $f(z^1) > f(z^2)$. Therefore, when $\chi < \chi_m$, a stationary sunspot equilibrium exists.

Now consider the case with $f'(z_s) < -1$. Since $f'(z_s) < 0$, there is an interval $[z_s - \varepsilon_1, z_s + \varepsilon_2]$, which satisfy $\varepsilon_1, \varepsilon_2 > 0$ and $f(z^1) > f(z^2)$ for $z^1 \in [z_s - \varepsilon_1, z_s]$ and $z^2 \in (z_s, z_s + \varepsilon_2]$.

$$\frac{z^2 - z_s}{z_s - z^1} < -f'(z_s) < \frac{z_s - z^1}{z^2 - z_s}$$

Since $f'(z_s) < -1$, the above condition can be reduced to $-f'(z_s) < \frac{z_s - z^1}{z_s^2 - z_s} = \frac{\varepsilon_1}{\varepsilon_2}$. There exist multiple solutions, $(\varepsilon_1, \varepsilon_2)$, satisfying $-f'(z_s)\varepsilon_2 < \varepsilon_1$ given $-f'(z_s) > 1$ and $\varepsilon_1, \varepsilon_2 > 0$. These solutions satisfy (50). Therefore, if $f'(z_s) < -1$, there exists a stationary sunspot cycle. \blacksquare

Proof of Proposition 6. Consider $z_t = f(z_{t+1})$. If $z_s > \bar{z}$ where \bar{z} solves $f'(\bar{z}) = 0$. In this case, there exist multiple equilibria. If $q^* \leq f(\bar{z})$, then there exist equilibria $\{z_t\}_{t=0}^\infty$ with $z_T \equiv \max\{z_t\}_{t=0}^\infty > q^*$ (bubble) which crashes to 0 (burst) as $t \rightarrow \infty$, where $T \geq 1$ and $z_T > z_0$. Then there exist equilibria with bubble-burst as a self-fulfilling crisis. Conditions for this case are shown as below. Similar to Corollary 3, consider take-it-leave-it offer with $-qu''/u' = \eta$ and $c(q) = q$. Then we have following difference equation:

$$z_t = f(z_{t+1}) \begin{cases} \frac{z_{t+1}}{1+i} \left\{ \frac{1-\sigma+\sigma\chi}{\chi} \alpha [u'(z_{t+1}) - 1] + 1 \right\} & \text{if } z_{t+1} < q^* \\ \frac{z_{t+1}}{1+i} & \text{if } z_{t+1} \geq q^* \end{cases} \quad (51)$$

Step 1: [Multiplicity i.e., $z_s > \bar{z}$ where \bar{z} solves $f'(\bar{z}) = 0$] Consider the following condition.

$$f'(\bar{z}) = \frac{1}{1+i} \left\{ \frac{\alpha(1-\sigma+\sigma\chi)}{\chi} [u'(\bar{z})(1-\eta) - 1] + 1 \right\} = 0$$

Since $z_s > \bar{z} \rightarrow u'(z_s) < u'(\bar{z})$, we have

$$u'(z_s) = 1 + \frac{i\chi}{\alpha(1-\sigma+\sigma\chi)} < \frac{1}{1-\eta} \left\{ 1 - \frac{\chi}{\alpha(1-\sigma+\sigma\chi)} \right\} = u'(\bar{z}).$$

This can be reduced as

$$\chi < \frac{\alpha\eta(1-\sigma)}{1+i-\eta(i+\alpha\sigma)}$$

Step 2: [Show $q^* \leq f(\bar{z})$] It is straightforward to show that $q^* < f(\bar{z})$ holds when

$$\chi < \frac{(1-\sigma)\alpha\eta(1+i)}{(1-\eta)^2q^* + (1+i)[(1-\eta)(3+i-\eta) - \alpha\sigma\eta]}$$

Therefore, when

$$0 < \chi < \min \left\{ \frac{(1-\sigma)\alpha\eta(1+i)}{(1-\eta)^2q^* + (1+i)[(1-\eta)(3+i-\eta) - \alpha\sigma\eta]}, \frac{\alpha\eta(1-\sigma)}{1+i-\eta(i+\alpha\sigma)} \right\}$$

there exist $\{z_t\}_{t=0}^\infty$ satisfying $z_T \equiv \max\{z_t\}_{t=0}^\infty > q^*$ and $\lim_{t \rightarrow \infty} z_t = 0$, where $T \geq 1$ and $z_T > z_0 > q^*/(1+i)$. \blacksquare

Proof of Proposition 7. A two period cycle result is presented and three-period case will follow. Let there exists a two-period cycle satisfying $w_1 < q^* < w_2$ where $w_j = z_j + \bar{b}_j$. Since $w_2 > q^*$, we have $z_2 = (1+i)z_1$ and $\bar{b}_2 = (1+r)\bar{b}_1$ where q_1 , \bar{b}_1 , and z_1 solve

$$u'(q_1) = 1 + \chi \frac{(1+i)^2 - 1}{\alpha(1-\sigma + \sigma\chi)}$$

$$\bar{b}_1 = [(1+\rho)^2 - 1]^{-1} \left\{ \frac{i\mu\sigma\chi}{1-\sigma + \sigma\chi} \left[1 - \frac{(1+i)^2}{\beta} \right] z_1 + \mu\alpha\sigma[u(q_1) - q_1] \right\}$$

and $z_1 = q_1 - \bar{b}_1$. This two-period cycle should satisfy $q_1 < q^*$ and $w_2 = (1+i)z_1 + (1+r)\bar{b}_1 > q^*$. For given $i > 0$ and $\chi > 0$, first one can be easily shown using

$$1 = u'(q^*) < u'(q_s) = 1 + \frac{i}{\alpha(1-\sigma + \sigma\chi)}\chi < 1 + \frac{(1+i)^2 - 1}{\alpha(1-\sigma + \sigma\chi)}\chi = u'(q_1)$$

since we have $u''(\cdot) < 0$. Now we also can check the latter using the below conditions

$$(1+\rho)q_1 > (1+i)z_1 + (1+\rho)\bar{b}_1 = w_2 > q^* > q_1 = z_1 + \bar{b}_1 \quad \text{if } \rho > i$$

$$(1+i)q_1 > (1+i)z_1 + (1+\rho)\bar{b}_1 = w_2 > q^* > q_1 = z_1 + \bar{b}_1 \quad \text{if } i > \rho.$$

The sufficient conditions to have $w_2 > q^*$ is $q_1 > q^*/(1+\rho)$ for $\rho > i$ and $q_1 > q^*/(1+i)$ for $i > \rho$. Since we have $dq_1/d\chi < 0$, there exist a three period cycle $q_1 = w_1 < q_s < q^* < w_2 < w_3$ when

$$0 < \chi < \frac{(1-\sigma)\alpha[u'(\frac{q^*}{1+i}) - 1]}{(1+i)^2 - 1 - \sigma\alpha[u'(\frac{q^*}{1+i}) - 1]}$$

where $\iota = \max\{i, \rho\}$. Now, let there exists a three-period cycle satisfying $q_1 = w_1 < q_s < q^* < w_2 < w_3$ where $w_j = z_j + \bar{b}_j$. Since $w_3, w_2 > q^*$, we have $z_2 = (1+i)z_1$, $z_3 = (1+i)^2 z_1$, $\bar{b}_2 = (1+\rho)\bar{b}_1$ and $\bar{b}_3 = (1+\rho)^2 \bar{b}_1$ where q_1 , \bar{b}_1 , and z_1 solve

$$u'(q_1) = 1 + \chi \frac{(1+i)^3 - 1}{\alpha(1-\sigma + \sigma\chi)}$$

$$\bar{b}_1 = [(1+\rho)^3 - 1]^{-1} \left\{ \frac{i\mu\sigma\chi}{1-\sigma + \sigma\chi} \left[1 - \frac{(1+i)^2}{\beta} \right] z_1 + \mu\alpha\sigma[u(q_1) - q_1] \right\}$$

and $z_1 = q_1 - \bar{b}_1$. This three-period cycle should satisfy $q_1 < q_s < q^*$ and $w_2 = (1+i)z_1 + (1+\rho)\bar{b}_1 > q^*$. For given $i > 0$ and $\chi > 0$, first one can be easily shown using

$$1 = u'(q^*) < u'(q_s) = 1 + \frac{i}{\alpha(1-\sigma+\sigma\chi)}\chi < 1 + \frac{(1+i)^3-1}{\alpha(1-\sigma+\sigma\chi)}\chi = u'(q_1)$$

since we have $u''(\cdot) < 0$. Now we also can check the latter using below conditions

$$\begin{aligned} (1+\rho)q_1 &> (1+i)z_1 + (1+\rho)\bar{b}_1 = w_2 > q^* > q_1 = z_1 + \bar{b}_1 & \text{if } \rho > i \\ (1+i)q_1 &> (1+i)z_1 + (1+\rho)\bar{b}_1 = w_2 > q^* > q_1 = z_1 + \bar{b}_1 & \text{if } i > \rho. \end{aligned}$$

The sufficient conditions to have $w_2 > q^*$ is $q_1 > q^*/(1+\rho)$ for $\rho > i$ and $q_1 > q^*/(1+\rho)$ for $i > \rho$. Since we have $dq_1/d\chi < 0$, there exist a three period cycle $q_1 = w_1 < q_s < q^* < w_2 < w_3$ when

$$0 < \chi < \frac{(1-\sigma)\alpha[u'(\frac{q^*}{1+\iota}) - 1]}{(1+i)^3 - 1 - \sigma\alpha[u'(\frac{q^*}{1+\iota}) - 1]}$$

where $\iota = \max\{i, \rho\}$. Again, the existence of a three-cycle implies the existence of cycles of all orders and chaotic dynamics by the Sarkovskii theorem and the Li-Yorke theorem. ■

Appendix B Empirical Appendix

This section provides robustness checks for empirical results. To check the sensitivity of the results, Table 4 and 5 repeat all the empirical analysis, reported in Table 1 and 2, using quarterly series instead of annual data. The results are similar to the benchmark analysis shown in Table 1 and 2.

Table 4: Effect of Required Reserve Ratio: Robustness Check (Quarterly)

$\Delta \sigma_t^{Roll}$	(Core PCE)	-32.753***	-4.504***	-3.164**

Note: **ffr** denotes federal funds rates, χ denotes required reserve ratio, and σ_t^{Roll} denotes cyclical volatility of real inside money balances. ***, **, and * denotes significance at the 1, 5, and 10 percent levels, respectively.

Lastly, this section provides robustness checks using alternative data set. Table 10 and 11 repeat the analysis using the alternative data, M1J from Lucas and Nicolini

(2015). Instead of the total checkable deposit, this analysis uses the deposit component of M1J. To get the deposit component of M1J, I subtract the currency component of M1 from M1J. The required reserve ratio is calculated by dividing required reserves by the deposit component of M1J. Again, the results are similar to the benchmark analysis shown in Table 1 and 2.

Table 10: Effect of Required Reserve Ratio: M1J

Price level	CPI		Core CPI		PCE		Core PCE	
Dependent variable: σ_t^{Roll}	OLS (1)	CCR (2)	OLS (3)	CCR (4)	OLS (5)	CCR (6)	OLS (7)	CCR (8)
χ	-0.106 (0.088)	-0.242*** (0.057)	-0.084 (0.087)	-0.225*** (0.059)	-0.114 (0.087)	-0.230*** (0.057)	-0.105 (0.086)	-0.235*** (0.058)
frr		0.895*** (0.091)		0.874*** (0.086)		0.846*** (0.089)		0.850*** (0.087)
Constant	0.061*** (0.010)	0.016** (0.007)	0.058*** (0.010)	0.014* (0.007)	0.060*** (0.010)	0.016** (0.007)	0.058*** (0.010)	0.015** (0.007)
Obs.	54	54	54	54	54	54	54	54
$adjR^2$	0.012	0.575	0.001	0.558	0.017	0.554	0.012	0.544
$\lambda_{trace}(r=0)$	15.629	52.816	15.705	52.469	15.445	52.454	15.454	51.933
5% CV	15.41	29.68	15.41	29.68	15.41	29.68	15.41	29.68
$\lambda_{trace}(r=1)$	3.011	15.583	2.720	15.651	2.834	15.363	2.628	15.342
5% CV	3.76	15.41	3.76	15.41	3.76	15.41	3.76	15.41

Note: For (1), OLS estimates are reported, and Newey-West standard errors with lag 1 are reported in parentheses. For (2) and (3), first-stage long-run variance estimations for CCR are based on the quadratic spectral kernel and Bayesian information criterion. The bandwidth selection is based on Newey-West fixed lag, $4 \times (T/100)^{2/9}$; **frr** denotes federal funds rates and σ_t^{Roll} denotes cyclical volatility of real inside money balances. ***, **, and * denotes significance at the 1, 5, and 10 percent levels, respectively.

Table 11: Unit Root Tests: M1J

		Phillips-Perron test		ADF test
		$Z(\rho)$	$Z(t)$	$Z(t)$ w/ lag 1
frr		-7.322	-1.899	-2.615
χ		-0.639	-0.549	-0.794
σ_t^{Roll}	(CPI)	-3.546	-1.345	-1.901
σ_t^{Roll}	(Core CPI)	-3.648	-1.361	-1.957
σ_t^{Roll}	(PCE)	-3.645	-1.361	-1.946
σ_t^{Roll}	(Core PCE)	-3.744	-1.376	-1.986
Δffr		-35.123***	-5.580***	-6.963***
$\Delta \chi$		-30.663***	-4.584***	-3.840***
$\Delta \sigma_t^{Roll}$	(CPI)	-14.619**	-2.816*	-2.770*
$\Delta \sigma_t^{Roll}$	(Core CPI)	-14.600*	-2.820*	-2.840*
$\Delta \sigma_t^{Roll}$	(PCE)	-14.926**	-2.847*	-2.851*
$\Delta \sigma_t^{Roll}$	(Core PCE)	-15.106**	-2.871*	-2.948**

Note: **frr** denotes federal funds rates, χ denotes required reserve ratio, and σ_t^{Roll} denotes cyclical volatility of real inside money balances. ***, **, and * denotes significance at the 1, 5, and 10 percent levels, respectively.

Appendix C Closed Form Solution for Calibration

This section provides closed-form solutions that are used for the calibration. The utility functions and the DM cost function for the parameterization are

$$U(X) = B \log(X), \quad u(q) = \frac{Cq^{1-\eta}}{1-\eta}, \quad c(q) = q.$$

The stationary equilibrium satisfies

$$u'(q) = Cq^{-\eta} = 1 + \frac{i\chi}{\alpha[1+i(1-\chi)]}$$

and the DM consumption is

$$q = \left[\frac{1}{C} \left\{ 1 + \frac{i\chi}{\alpha(1-\sigma+\sigma\chi)} \right\} \right]^{-\frac{1}{\eta}}.$$

The real balance of aggregate money is equal to the DM consumption i.e., $z = q$ and the real balance z to output ratio is given by

$$Z \equiv \frac{z}{y} = \frac{z}{B + \sigma\alpha q}.$$

A derivative of z with respect to i is

$$\begin{aligned} \frac{\partial z}{\partial i} &= \frac{\partial q}{\partial i} = \frac{-\chi}{\alpha\eta(1-\sigma+\sigma\chi)} q^{\eta+1} \\ \frac{\partial Z}{\partial i} &= \frac{B}{(B + \sigma\alpha q)^2} \frac{\partial q}{\partial i} \end{aligned}$$

The elasticity of aggregate money with respect to i is given by

$$\frac{\partial \log(Z)}{\partial \log(i)} = \frac{i}{Z} \frac{\partial Z}{\partial i} = \frac{Bi}{q(B + \sigma\alpha q)} \frac{\partial q}{\partial i}.$$

Model 2

When $\mu > 0$, unsecured credit limit is determined by

$$\bar{b} = \left(1 - \frac{i\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} \right)^{-1} \left[\frac{\mu\sigma\alpha}{\rho} \{u(q) - q\} - \frac{i\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} q \right]$$

When $\mu > 0$, the real balance of aggregate money is

$$z = q - \bar{b}$$

and the derivative of unsecured credit with respect to i is

$$\begin{aligned}\frac{\partial \bar{b}}{\partial i} = & \frac{\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} \left\{ 1 - \frac{i\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} \right\}^{-2} \left[\frac{\mu\rho\alpha}{\rho} \{u(q) - q\} - \frac{i\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} q \right] \\ & + \left\{ 1 - \frac{i\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} \right\}^{-1} \left[\frac{\mu\sigma\alpha}{\rho} \{u'(q) - 1\} - \frac{i\mu\sigma\alpha}{\rho(1-\sigma+\sigma\chi)} \right] \frac{\partial q}{\partial i} \\ & - \left\{ 1 - \frac{i\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} \right\}^{-1} \frac{\mu\sigma\chi}{\rho(1-\sigma+\sigma\chi)} q\end{aligned}$$

and the derivative of aggregate money real balances with respect to i is

$$\frac{\partial z}{\partial i} = \frac{\partial q}{\partial i} - \frac{\partial \bar{b}}{\partial i}.$$

The aggregate money real balances z to output ratio is

$$Z \equiv \frac{z}{y} = \frac{z}{B + \sigma\alpha q}$$

derivative of Z with respect to i is

$$\frac{\partial Z}{\partial i} = \frac{-\sigma\alpha z}{(B + \sigma\alpha q)^2} \frac{\partial q}{\partial i} + \frac{1}{B + \sigma\alpha q} \frac{\partial z}{\partial i}$$

and the elasticity of aggregate money with respect to i is

$$\frac{\partial \log(Z)}{\partial \log(i)} = \frac{i}{Z} \frac{\partial Z}{\partial i}$$
